<sup>26</sup> **The LHC and CMS  
Machine**

<sup>28</sup> In this chapter, the working and the design parameters of **Large Hadron  
29 Collider (LHC)** and its one of main purpose detector, Compact Muon  
30 Solenoid (CMS), are briefly described.

<sup>31</sup> **1.1 The Large Hadron Collider**

<sup>32</sup> The famous quote “history repeats itself” applies well to the **High Energy  
33 Physics (HEP)** experiments. The starting point of experimental particle  
34 physics is the Rutherford  $\alpha$ -particle scattering, which is suggested by  
35 Ernest Rutherford and carried out by the two assistant Hans Geiger and  
36 Ernest Marsden in early 20th century [1]. In this experiment Rutherford  
37 suggested to aim the beam of  $\alpha$ -particles to the thin gold foil and using  
38 the experimental findings they suggested the well known structure of  
39 today’s atom, in which the most of mass centered at core of atom which  
40 is known as nucleus and the electrons rotates around the nucleus. Even  
41 now we are doing the same thing just the method changed from “natural  
42 accelerator”<sup>1</sup> to the “man-made” accelerator that can accelerate particles  
43 with the velocity close to the speed of light. The design and working of  
44 the accelerator has changed a lot over a period of time in going from MeV  
45 to GeV and in the TeV range. Now, these machines are not only used  
46 in **HEP** experiments, but also extends their arenas to treating human  
47 beings from cancer therapy, radioisotope production, 3-D x-ray, also to  
48 the industry for uses like material processing, sterilization, security scan,

<sup>1</sup>radioactivity and cosmic rays

49 water treatment, and many more.

50 The LHC is a hadron collider which can accelerate two proton beams,  
51 moving in opposite direction, to a maximum of 14 TeV energy in a 26.7  
52 km long tunnel which is about 100 m underground. The LHC is the latest  
53 and most-powerful accelerator ever built. It is a proton-proton collider  
54 built to improve our understanding of fundamental physics. It started  
55 on 21<sup>st</sup> October 2008 and is positioned in the same tunnel that earlier had  
56 Large Electron Positron Collider (LEP). The LEP collaboration decided  
57 to switch to hadron collider because of following advantages:

- 58 • Hadron collider can reach a higher Center Of Mass (COM) energy,  
59 because of much lower synchrotron radiation <sup>2</sup> emitted by hadrons  
60 as compared to electrons. Synchrotron radiation loss is directly  
61 proportional to  $(Energy/mass)^4$ .
- 62 • As hadrons are composite particles, they allow us to scan over wide  
63 range of energies.

64 For any particle accelerator, there are mainly three components. In  
65 case of LHC, they are:

- 66 • Beam pipes
- 67 • Accelerating structure
- 68 • Magnet system

### 69 1.1.1 Beam Pipes

70 At LHC, there are two beam pipes each with diameter  $\approx 6.3$  cm in which  
71 proton beams travel in opposite directions. To avoid beam instability  
72 and loss of beam particles due to collision with gas molecules; the beam  
73 pipes are kept at ultra-high vacuum<sup>3</sup>  $1.013 \times 10^{-13}$  bar pressure.

---

<sup>2</sup>The radiation emitted by a charged particle during acceleration in a circular path is known as synchrotron radiation. As the particles loses energy in emission of this radiation an additional energy must be provided to keep the beam at constant energy.

<sup>3</sup>At LHC, three different vacuum systems are used. First one is used for beam pipe; second one for insulating the cryogenically cooled magnets and third one is used for insulating the helium distribution. In the latter two it just acts as a thermal insulator as the cryogenic parts are kept at 1.9 K ( $-271.3^{\circ}C$ )

74    **1.1.2 Accelerating Structure**

75    Another main part of any particle accelerator is its accelerating struc-  
76    ture. A accelerator in the TeV range can not start from rest and go to  
77    the TeV range in one go; it should go into several stages depending on the  
78    energy. At LHC, the journey of proton starts with grabbing the proton  
79    from Hydrogen gas and subsequently going into 5 different stages. The  
80    stages can be decreased but could not be decreased to just one. Here,  
81    at LHC there are five different stages before reaching to LHC and in be-  
82    tween it serves several other experiments at each stage, which are shown  
83    pictorially in Figure 1.1. The stages for proton acceleration are:

- 84    • Grab proton source: The source of proton is Duoplasmatron [2]. It  
85    strips electron from hydrogen gas and creates a plasma of protons,  
86    electrons and molecular ions. This plasma expands towards the ex-  
87    traction electrodes and a proton beam is formed. This feeds protons  
88    to LINAC2.
- 89    • LINAC2 (Linear accelerator-2): It is the starting point of proton's  
90    journey in the LHC accelerator complex. Here, protons reaches to  
91    an energy of  $50 \text{ MeV}$  using the radio-frequency (RF) cavities<sup>4</sup> where  
92    they also gains 5% in mass. LINAC2 further feeds to the Proton  
93    Synchrotron Booster (PSB).
- 94    • PSB: It takes  $50 \text{ MeV}$  proton beams from LINAC2 and accelerate  
95    them to  $1.4 \text{ GeV}$  for injection into Proton Synchrotron (PS).
- 96    • PS: It is one of key component in the LHC accelerator complex. It  
97    increases the energy of protons up-to  $25 \text{ GeV}$  and feeds to super  
98    proton synchrotron.
- 99    • Super Proton Synchrotron (SPS): It has a circumference of  $7 \text{ km}$   
100   where protons are accelerated to an energy of  $450 \text{ GeV}$ . Then via  
101   two transmission line protons are then injected into LHC ring.
- 102   • LHC: It grabs two proton beams from SPS which are injected into  
103   opposite directions in parallel pipes. In LHC, proton beams can be  
104   accelerated up-to  $7 \text{ TeV}$ .

105   The CERN accelerator complex is shown in Figure 1.2.

---

<sup>4</sup>A RF cavity is an metallic cavity that accelerates the charged particles using the electromagnetic field.

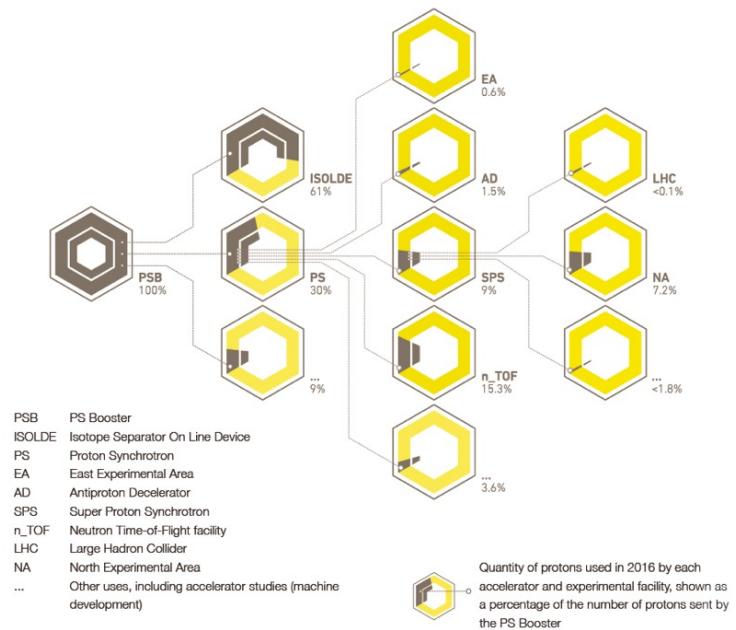

Figure 1.1: Other experiments at the LHC accelerating chain [3]

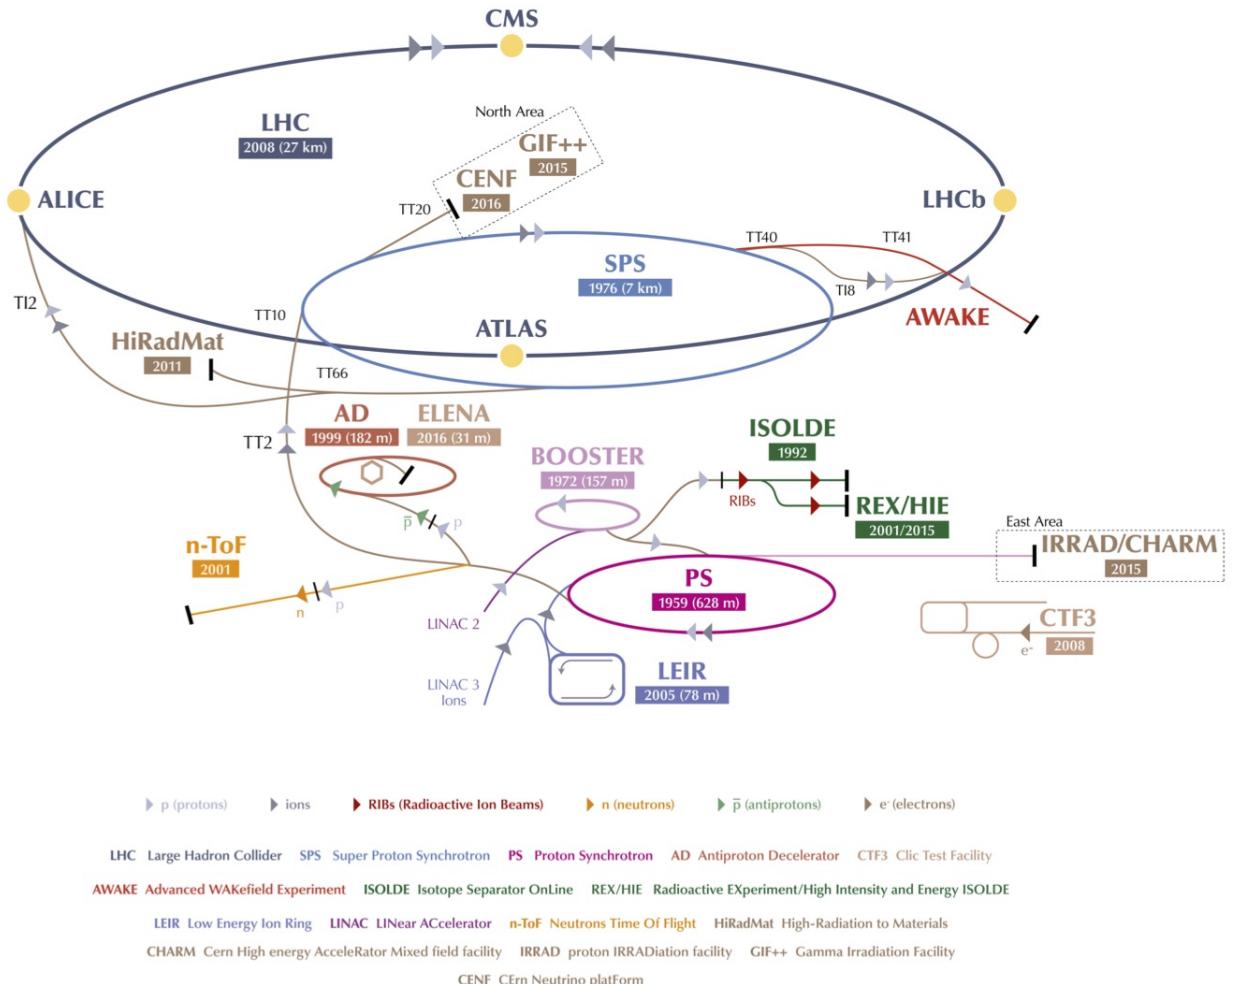

Figure 1.2: LHC accelerator chain along with all its other experiments which uses proton beam from other part of accelerator either from PSB, PS or SPS[4]

### 106 1.1.3 Magnet System

107 As the LHC is a circular collider; magnet system is one of the core parts  
108 and gives particles a circular trajectory in the LHC beam pipes. To be  
109 economical LHC has been made in eight arcs and eight straight sections  
110 instead of a perfect circle. Apart from bending the beam, it is also  
111 necessary to focus the beam as the same charge protons try to diverge.  
112 To focus the beam a pair of quadrupole magnets is used. One focuses the  
113 beam width while other focuses the beam height. Quadrupole magnet  
114 geometry is shown in Figure 1.3. A total of 858 quadrupole magnets  
115 are installed in LHC to keep the beam focused. Sextupole magnets are  
116 also used for proper focusing as every proton in the beam is not exactly  
117 with the same energy and on the same path. Several other magnetic  
118 multi-poles are used to keep the beam focused in case the beam suffers  
119 from gravitational interactions over protons, electromagnetic interactions  
120 among bunches, electron clouds from pipe wall, and so on. Different types  
121 of magnets used in LHC are listed here [5]. Besides, there are eight sets  
122 of “inner triplets” used at the four interaction points (IPs) to focus the  
123 beams while colliding to increase the luminosity. Here the size of bunch  
124 goes from 0.2 mm to 17  $\mu\text{m}$  at the interaction point of ATLAS or CMS.  
125 At the interaction point of ALICE or LHCb it is 71  $\mu\text{m}$ . Summary of  
important parameters of LHC is given in Table 1.1.

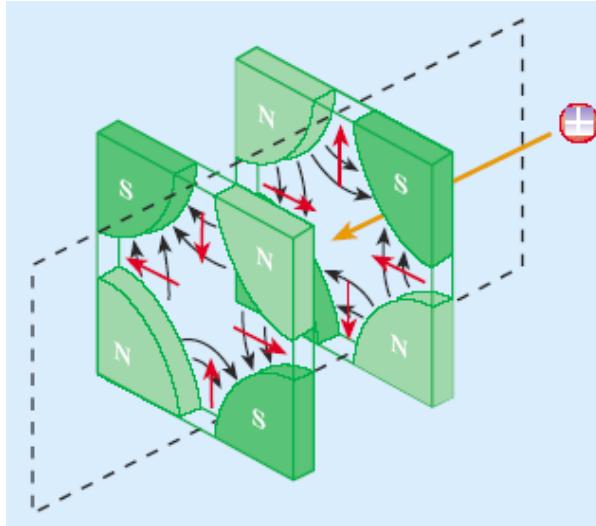

Figure 1.3: Pair of quadrupole magnets.

Parameters	Value
Circumference of LHC ring	26658.883 m
Maximum dipole magnetic field	8.33 T
Dipole operating temperature	1.9 K
Maximum stored energy per beam (nominal)	362 MJ
Maximum stored energy per beam (2012)	143 MJ
Maximum stored energy per beam (2016)	266 MJ
Beam energy at Injection	450 GeV
Beam energy at collision (nominal)	7 TeV
Beam energy at collision (2012)	4 TeV
Beam energy at collision (2016)	6.5 TeV
Maximum instantaneous luminosity (nominal)	$10^{34} \text{ cm}^{-2} \text{ s}^{-1}$
Maximum instantaneous luminosity (2012)	$7.7 \times 10^{33} \text{ cm}^{-2} \text{ s}^{-1}$
Maximum instantaneous luminosity (2016)	$1.4 \times 10^{34} \text{ cm}^{-2} \text{ s}^{-1}$
Number of bunches per proton beam (nominal)	2808
Number of bunches per proton beam (2012)	1380
Number of bunches per proton beam (2016)	2076
Maximum number of protons per bunch	$1.6 \times 10^{11}$
Protons/bunch (average at start of collision) (nominal)	$1.15 \times 10^{11}$
Protons/bunch (average at start of collision) (2012)	$1.5 \times 10^{11}$
Protons/bunch (average at start of collision) (2016)	$1.1 \times 10^{11}$
Bunch collision frequency (nominal)	40 MHz
Bunch collision frequency (2012)	20 MHz
Bunch collision frequency (2016)	40 MHz
Bunch length (at injection)	1.7 ns
Bunch length (at collision)	1.05 ns
Energy spread (at injection)	$1.9 \times 10^{-3}$
Energy spread (at collision)	$0.45 \times 10^{-3}$
Half crossing angle (nominal)	$143 \mu\text{rad}$
Half crossing angle (2012)	$146 \mu\text{rad}$
Half crossing angle (2016)	$185 \mu\text{rad}$
$\beta^*$ (nominal)	0.55 m
$\beta^*$ (2012)	0.6 m
$\beta^*$ (2016)	0.4 m
RMS beam size at IP1 & IP5	$17 \mu\text{m}$
RMS beam size at IP2 & IP8	$71 \mu\text{m}$
$\epsilon_n$ (transverse emittance, rms, normalized) (at injection)	$3.5 \mu\text{m}$
$\epsilon_n$ (transverse emittance, rms, normalized) (at collision point)	$3.75 \mu\text{m}$
total longitudinal emittance (at injection)	1.0 eVs
total longitudinal emittance (at collision)	2.5 eVs
Average mean pile-up (nominal)	25
Average mean pile-up (2012)	20
Average mean pile-up (2016)	40
Energy loss per turn at 14 TeV	7 keV
Energy loss per turn for electrons at 104.6 GeV	40,000 keV

Table 1.1: LHC technical parameters for proton-proton collisions: nominal, 2012 and 2016 values.[6, 7, 8, 9].

<sup>127</sup> **1.1.4 Few key requirements**

The HEP collider is mainly characterized by the two parameters: center of mass (COM) energy and the luminosity. The production rate of heavier particles like Higgs increases with COM energy. The luminosity is proportional to the number of events per second so it should be maximized. Luminosity is defined as:

$$L = \frac{k_b N_b^2 f_{rev} \gamma}{4\pi \epsilon_n \beta^*} \quad (1.1)$$

<sup>128</sup> where,

<sup>129</sup>  $k_b$  is the number of bunches per ring,

<sup>130</sup>  $N_b$  is the number of protons per bunch,

<sup>131</sup>  $f_{rev}$  the revolution frequency,

<sup>132</sup>  $\epsilon_n$  is the normalized RMS transverse beam emittance (same in both )

<sup>133</sup>  $\beta^*$  is the beta-function at the interaction point

<sup>134</sup>

<sup>135</sup> Based on the definition of luminosity, we can maximize it by following  
<sup>136</sup> means:

- <sup>137</sup> • By decreasing beam emittance,  $\epsilon_n$ .
- <sup>138</sup> • By improving the cryogenic system. As the factor  $k_b.N_b$  is limited  
<sup>139</sup> by thermal energy produced by synchrotron radiation.
- <sup>140</sup> • By decreasing beam-beam effect [10, 11]. As it scales with  $N_b/\epsilon_n$   
<sup>141</sup> which causes the spread in betatron tunes [12].
- <sup>142</sup> • Also, the space charge [13] scales with  $N_b/\epsilon_n$ .

<sup>143</sup> **1.2 Experiments at the LHC**

<sup>144</sup> In LHC there are four IPs where two proton beams are made to collide.

<sup>145</sup> At every IP one detector is placed. They are ATLAS, CMS, ALICE, and

<sup>146</sup> LHCb as shown in Figure 1.4. Also, there are two more small detectors

<sup>147</sup> LHCf and TOTEM installed close to the IP of the two main detectors

<sup>148</sup> ATLAS and CMS respectively.

<sup>149</sup> **ATLAS** (A Toroidal LHC Apparatus) and **CMS** (Compact Muon Solenoid)  
<sup>150</sup> are large general-purpose<sup>5</sup> detectors having similar design and similar

---

<sup>5</sup>Here, general purpose means this machines will be used for many different kind of physics searches.

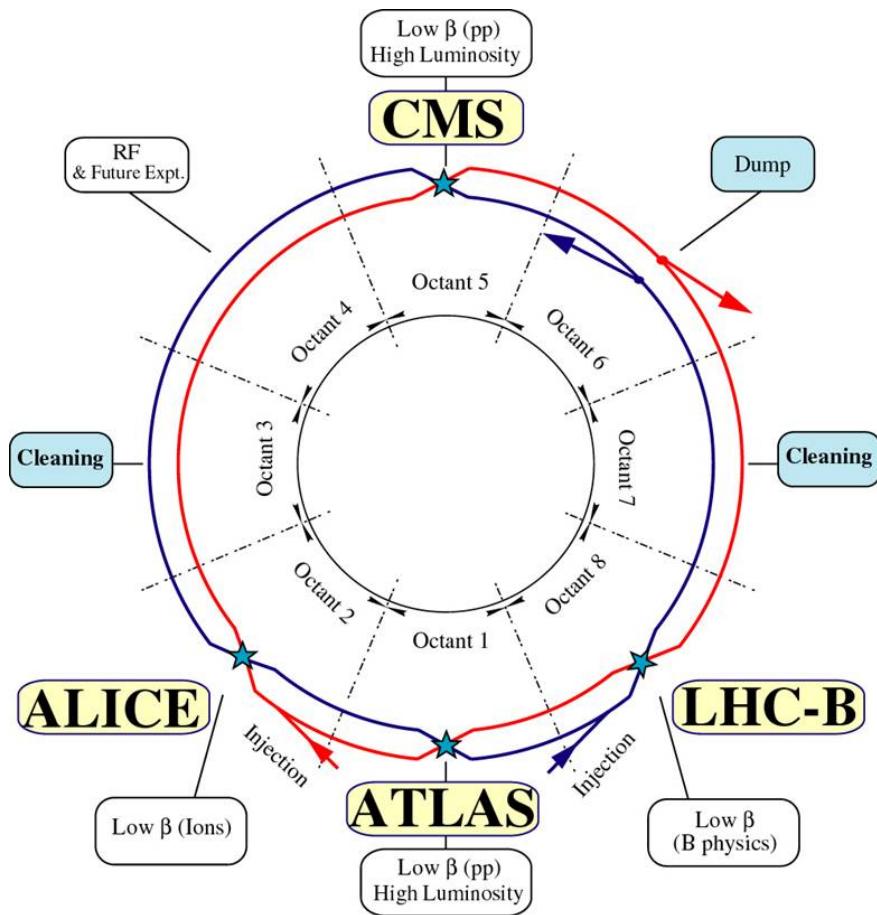

Figure 1.4: LHC geometry with arcs and straight sections.

151 goal. CMS detector will be described in detail in Section 1.3. The main  
152 difference in the two is in their magnet systems. One additional choice  
153 that affects this is the momentum resolution for muons. The momentum  
154 resolution for muons,  $\Delta p_T/p_T$ , are proportional to  $B^{-1}L^{-2}$ , where B is  
155 magnetic field and L is distance of momentum measurement from the  
156 IP of detector. So, To improve the momentum resolution there are two  
157 possible choices.

- 158 1. Increase the magnetic field with compact design, or  
159 2. Work with low magnetic field with long lever arm, L

160 There is also a third possibility to improve the momentum resolution  
161 by increasing the leaver arm as well as magnetic field, but it increases the  
162 cost of the detector by several factors. So, CMS chooses the first point,  
163 i.e., to increase the magnetic field with compact design<sup>6</sup> while ATLAS  
164 chooses the design with low magnetic field with long lever arm.

165 **ALICE** (A Large Ion Collider Experiment) is a heavy-ion detector.  
166 It is specially designed for the study of strongly interacting matter at  
167 high densities in quark-gluon plasma phase.

168 **LHCb** (Large Hadron Collider beauty) is made asymmetrically with  
169 respect to the IP of the detector. It is made specially to study the slight  
170 differences between the matter-antimatter through the study of b-quarks.

171 **LHCf** (Large Hadron Collider forward) and **TOTEM** (TOTal cross-  
172 section, Elastic scattering and diffraction dissociation Measurement at  
173 the LHC) are located near ATLAS and CMS respectively, for the study  
174 of forward physics.

### 175 1.3 CMS Experiment

176 In the HEP detectors there are two different categories of conditons are  
177 imposed. They are:

- 178 • restrictions imposed from the accelerator conditions.  
179 • restrictions because of physics goal.

180 Restrictions imposed on detector from the LHC are:

---

<sup>6</sup>This is why there is word **compact** in the name of CMS.

- **High luminosity delivered by LHC:** As the delivered luminosity is high this implies every-time the two proton bunches cross each other there will be more than one p-p interactions<sup>7</sup>. This is one of greatest challenges. This implies more than 1000 particles passes through detector during every p-p collision. This imposes condition that the detector should be highly granular this results with increase number of channels that should be synchronized with each other.
- **Event rate:** At LHC, the two proton bunches crosses each other at every 25 ns. So, the response time for all the sub-system of detector should be less than 25 ns.
- **Produced radiation:** At every 25 ns the detectors are bombarded with more than 1000 particles so all the sub-detectors should be radiation hard including its electronics, cables, glue, screws, and so on.

Restrictions imposed on detector from physics goal are:

- Good muon identification and momentum resolution ( $\approx 1\%$  at 100 GeV).
- Efficient triggering and tracking of b-jets and  $\tau$ 's.
- High resolution electromagnetic calorimeter to detect electrons and photons.
- Good missing transverse energy resolution and di-jet mass resolution requires a “hermetic” hadron calorimeter with full geometric coverage and fine lateral segmentation.

Based on the above condition CMS detector was designed in cylindrical shape having each detector on top of other with beam pipe at center. To have full geometric coverage it is designed with a barrel region and two endcap regions. Main part of the CMS detector is its superconducting magnet system with a high magnetic field of 4 Tesla to accurately

---

<sup>7</sup>More than one p-p interaction in one bunch crossing is known as pile-up. It can be theoretically calculated as the product of inelastic p-p cross-section ( $\sigma_{inel}$ ), instantaneous luminosity ( $L$ ) and the mean time interval between two collision, ( $< t >$ ).

$$mean\ pile-up = \sigma_{inel} \times L \times < t > \quad (1.2)$$

209 measure the high momentum particles and its muon system. Muon sys-  
 210 tem kept outside the magnet but sandwiched in its return yoke. While  
 211 the tracking system and calorimeters are placed inside the magnet. CMS  
 detector design is shown in Figure 1.5.

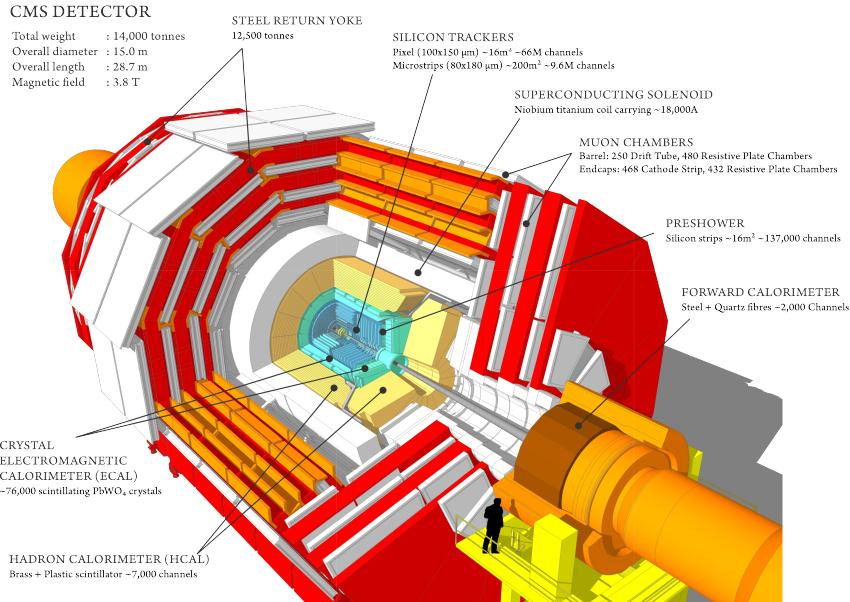

Figure 1.5: CMS detector drawing

212

### 213 1.3.1 Coordinate System

Right handed coordinate system is used having origin at the nominal IP (Figure 1.6). Z-axis is along the beam direction in such a way so that x-axis will point radially to the center of LHC ring and y-direction is pointing upwards. The azimuthal angle,  $\phi$ , is measured in x-y plane from x-axis and the polar angle,  $\theta$ , is measured from z-axis. Instead of describing a particle at some polar angle we prefer to use the variable pseudo-rapidity. It is defined as

$$\eta = -\ln[\tan(\theta/2)] \quad (1.3)$$

214 In hadron collider use of pseudo-rapidity is motivated from the invariance  
 215 of its difference,  $\Delta\eta$ . Also, the particle density remains constant in barrel  
 216 region of detector measured in equal rapidity intervals.

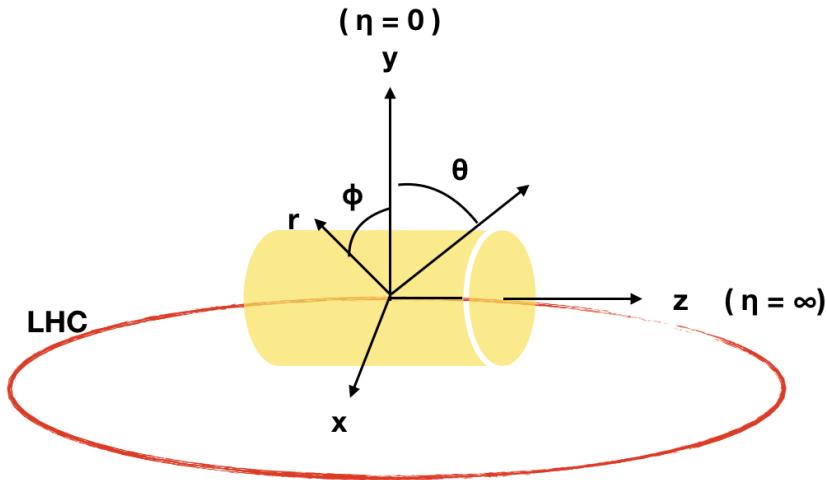

Figure 1.6: Right handed coordinate system used by CMS.

### <sup>217</sup> 1.3.2 CMS sub-systems

#### <sup>218</sup> Magnet

<sup>219</sup> Magnet system of CMS consists of a superconducting solenoid magnet  
<sup>220</sup> with 3.8 T magnetic field. It is 12.5 m in length and 6 meter in inner  
<sup>221</sup> diameter. The high magnetic field ensures the appropriate bending power  
<sup>222</sup> of the high-energy charged particles to precisely measure its momentum.  
<sup>223</sup> It is shown separately in Figure [1.7](#).

#### <sup>224</sup> Tracker

<sup>225</sup> Tracker is the first detector that encounter the particles emerging from  
<sup>226</sup> the p-p collision. Its purpose is to measure precisely the tracks of all  
<sup>227</sup> particles passing through it. It consists of 3 layers of silicon pixel detector  
<sup>228</sup> to precisely measure the primary vertex, secondary vertex and the impact  
<sup>229</sup> parameter along with 10 layers of silicon micro-strip detector. Tracker  
<sup>230</sup> has length of 5.8 m and outer diameter 2.6 m.

#### <sup>231</sup> Calorimetry

<sup>232</sup> In general, calorimeter is a device that measure energy of particles by de-  
<sup>233</sup> positing them into it. In CMS its divided into Electromagnetic CALorime-  
<sup>234</sup> ter (ECAL) and Hadronic CALorimeter (HCAL). ECAL as the name

Figure 1.7: CMS Magnet system

235 suggest its designed to measure the particles that primely interacts via  
 236 electromagnetic interaction while HCAL is designed to measure particles  
 237 that interacts via strong nuclear interactions.

238  
 239 ECAL is placed after tracker for detecting the electrons and photons. It  
 240 is made from lead tungstate ( $PbWO_4$ ) having coverage upto  $\eta < 3.0$  in-  
 241 cluding pre-shower system in forward region. The scintillation produced  
 242 in barrel region is detected by Avalanche photo-diodes and in endcaps it  
 243 is collected by vacuum photo-triodes. In terms of radiation length<sup>8</sup>,  $X_0$ ,  
 244 its thickness is  $25X_0$  which guarantees almost full shower containment.

245  
 246 In between ECAL and magnet system, brass/scintillator sampling HCAL  
 247 with coverage upto  $\eta < 3.0$  is placed. To have a full geometric coverage  
 248 HCAL is extended upto  $\eta < 5.0$  using forward sampling iron/quartz-fibre  
 249 calorimeter. This is crucial to measure the (missing) transverse energy  
 250 of the event.

---

<sup>8</sup>define it.

251    **The Muon System**

252    From the name of CMS detector its evident that the precise detection of  
253    muons is one of main target of CMS detector. The presence of muons in  
254    the final state in many interesting physics like the decay of Higgs boson  
255    into ZZ to 4 leptons. Specially, the case in which all 4 leptons are muons  
256    are known as “gold plated” as we can detect muons efficiently over high  
257    background at LHC. So, the detection and efficient reconstruction is very  
258    important for muons. At CMS, muon system has mainly three functions.  
259    They are identification of muons, momentum measurement and triggering.  
260    The strong superconducting magnet system with its return yoke of  
261    CMS also helps use to acquire good momentum measurement and trig-  
262    gering capabilities. The return yoke of magnet system also serves as the  
263    hadron absorber. The cross-sectional view of muons system is shown in  
264    Figure 1.8. It is described in details in Chapter ??

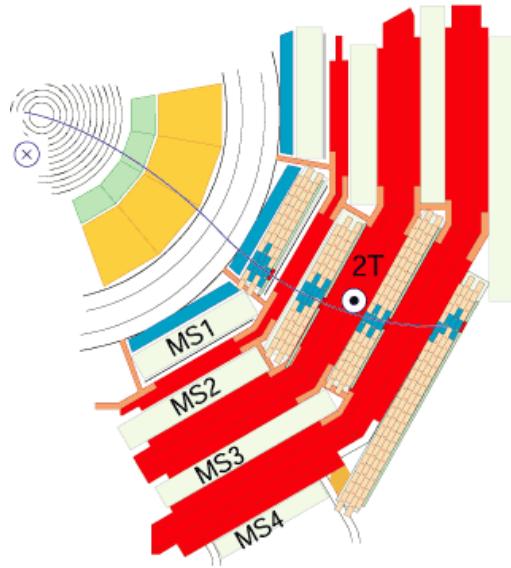

Figure 1.8: A muon leaves curved trajectory in LHC and the bending changes as the magnetic field direction of solenoid inside and outside are opposite.

265    **1.3.3 CMS Trigger and Data Acquisition system**

266    In CMS, every second about 1 billion p-p collision is happening. But,  
267    till now we don't have a switch with the required bandwidth that can

268 transfer huge data for further processing, and even if we have one, then  
269 there is only few fraction of data that are interesting for new physics or  
270 help to understand the existing one as most of the collisions are the low-  
271 energy glancing collision instead of head on interaction. So, the concept  
272 of trigger was introduced first by ZEUS experiment [14] to select the  
273 potentially interesting events that can reduce the event rate to just few  
274 hundreds such that it will be possible to store and transfer that data  
275 for further analysis. The trigger is designed in such a way that it can  
276 efficiently accept the interesting events and rejects the non-interesting  
277 events.

278 The CMS trigger system was designed in two steps, level 1 (L1) trig-  
279 ger which is custom hardware process running synchronously with the  
280 LHC bunch crossing frequency of 40 MHz and the High Level Trigger  
281 (HLT) [15]. L1 trigger selects the events based on the information of  
282 calorimeter and muon system. But this decision can't take place within  
283 25 ns so a latency of  $3.2 \mu s$  was added. The maximum allowed frequency  
284 at L1 stage is 100 kHz. Then the complete information is sent to HLT  
285 processing farm to reduced the event rate to  $\sim 100$  Hz. The remaining  
286 information is sent to Tier-0 centers to store and use it for offline analysis.

#### 287 1.3.4 CMS Offline Computing

288 Once the decision was taken by trigger system it is ready to be analyzed  
289 offline. But, before that the raw data need to be processed to convert it  
290 into understandable physics objects like electrons, muons, photons, jets,  
291 and so on. This step is known as object reconstructions which is most  
292 CPU intensive task in the data processing chain of CMS. In this step  
293 one need to reconstruct the primary vertices, track finding algorithms,  
294 identify electrons, photons, muons, reconstruct jets, apply b-tagging al-  
295 gorithm to reconstruct b-jets, run detector specific filtering and so on. To  
296 perform all these steps CMS developed its own software which is known  
297 as CMSSW. This is based on Event Data Model (EDM) centered around  
298 the concept of event. Here, an event is a C++ object container for all  
299 raw and reconstructed data related to a certain collision. These events  
300 are stored in ROOT files [16]. The CMSSW event processing model con-  
301 sists of one executable called cmsRun, and many plug-in modules. These  
302 modules contain all the necessary codes for the event processing such as  
303 calibration and reconstruction algorithms [17]. To do the analysis, we  
304 also need Monte Carlo (MC) simulations of various Standard Model pro-  
305 cesses and new physics models. MC events are generated at parton level.  
306 Then showering and hadronization is applied and finally these events are

307 put through the GEANT4 [18] based CMS detector simulation. The re-  
308 sult is data similar to what one obtains from the actual detector. This  
309 MC data can then also be reconstructed as if it were actually detector  
310 data.
